In this project we use object orientation to model the solar system. We implement the solar system using a C++ class based approach, and solve the differential equations given by Newton's laws to obtain the full motion. We solve the discretized version of the differential equations using Euler's method and the Velocity Verlet method and compare the efficiency and numerical stability. We also check the accuracy of our results using physical laws such as conservation of energy and momentum.

We find that the time usage of both the Euler and Verlet methods scale roughly linearly with the number of integration points. We find that the Euler method provides poor results in the case of elliptical orbits, and scales poorly with the time step $\Delta t$, while the Verlet method has a global error of the order $\mathcal{O}(\Delta t^2)$. In addition, we find that the stability of our solar system is highly dependent on the sun being much more massive than the other celestial objects. Finally, we study the perihelion precession of Mercury and find a perturbation in the orbit only explained by a relativistic correction. We find that our relativistic correction produces a precession of roughly 47" per century compared to the pure newtonian force.

## I. INTRODUCTION

In this project we study the solar system consisting simply of the Earth and the sun, and the full solar system consisting of all 8 planets in addition to Pluto and the sun. We model each celestial object as a point particle in 3-dimensional space, and Newton's laws give us a simple ordinary differential equation governing the time evolution of each celestial object. A class based approach in C++ allows us to easily extend the code to obtain the full motion of the solar system. We solve the differential equations numerically using a length and time scale appropriate for our problem.

In particular, we will be implementing Euler's method and the Velocity Verlet method. Before comparing the results, we will note that Euler's method, though simple, can be quite numerically unstable. The Velocity Verlet method is well suited to our problem, and gives a good tradeoff betweeen numerical efficiency and accuracy.

Finally we will examine the perihelion precession of Mercury. One of the early successes of the general theory of relativity was to explain the precession of Mercury as it orbited the sun, after all other pure newtonian effects had been accounted for. We will be modelling this by adding a relativistic correction, and checking to see whether this correction gives us an appropriate perturbation of the orbit.

―――――――

## II. THEORY AND METHODS

### A. Newton's law of gravitation

Newton's law of gravitation states that for two objects of mass $m_1$ and $m_2$, the gravitational force on object 1 from object 2 is given by [? ],

$$\boldsymbol{F_{1,2}} = \frac{Gm_1m_2}{r^2}\boldsymbol{u_r} = \frac{Gm_1m_2}{r^3}\boldsymbol{r} \tag{1}$$

where $G$ is the gravitational constant and $\boldsymbol{u_r} = \boldsymbol{r}/r$ is a radial unit vector. $\boldsymbol{r}$ is a radial vector pointing at object 2 and $r = |\boldsymbol{r}|$ is the distance. Newton's third law gives us that the force on object 2 from object 1 is $\boldsymbol{F_{2,1}} = -\boldsymbol{F_{1,2}}$. Newton's third law gives us the differential equation governing the motion of object 1

$$\ddot{\boldsymbol{r}}(\boldsymbol{t}) = \boldsymbol{a}(\boldsymbol{t}) = \boldsymbol{F_{1,2}}(t, \boldsymbol{r}(t))/m_1, \tag{2}$$

where $\boldsymbol{a}$ is the acceleration, and we can solve this equation to find the motion $\boldsymbol{r(t)}$. For a two-body system this equation will produce closed elliptical orbits around a common center of mass.

If we assume that the orbit of object 2 around object 1 is circular we know that the force obeys the following equation

$$F_{2,1} = \frac{Gm_1m_2}{r^2} = \frac{m_1v_1^2}{r}, \tag{3}$$

which implies that

$$v_1^2 r = Gm_2. \tag{4}$$

Introducing 1 AU $= 1.5 \cdot 10^{11}$m; the distance from the Earth to the sun, we let object 1 be the sun and object 2 the Earth, and we obtain

$$v_{earth}^2 r = GM_\odot = 4\pi^2 AU^3/yr^2, \tag{5}$$

where I have used that the circular velocity of the Earth is $v_{earth} = 2\pi r/T = 2\pi AU/yr$. This lets us rewrite our differential equation in a more natural length scale for the solar system. For a solar system with 1 sun and 9 planets (including Pluto) we may write the differential equation governing the motion of each celestial object $i$ as

$$\ddot{\boldsymbol{r}}_i = \frac{\boldsymbol{F_{tot}}}{M_i} = \sum_{j \neq i} \frac{\boldsymbol{F_{i,j}}}{M_i}$$
$$= -\sum_{j \neq i} \frac{4\pi^2 M_j}{r^3} \boldsymbol{r_{i,j}} \quad , \tag{6}$$

where the acceleration $\boldsymbol{a} = \ddot{\boldsymbol{r}}$ is measured in units of $4\pi^2 AU/yr^2$. The minus sign stems from the fact that the position vectors point in the opposite direction of the force vectors. We may also measure the mass of each celestial object by solar mass, by setting $M_\odot = 1$.

## B. Ordinary differential equations

We discretize the differential equation by setting the number of time steps $n$, the number of years we want to evolve the system $y$ and the length of each time step $\Delta t = y/n$. The simplest way of solving equation (6) numerically is Euler's method [? ]:

$$\boldsymbol{v_{i+1}} = \boldsymbol{v_i} + \Delta t \cdot \boldsymbol{F_{tot}}/M_i \qquad i = 0, 1, 2, .., n-1$$
$$\boldsymbol{x_{i+1}} = \boldsymbol{x_i} + \Delta t \cdot \boldsymbol{v_i} \tag{7}$$

A significant improvement would be the Velocity Verlet algorithm. For a second order differential equation of the form

$$\frac{d^2}{dt^2}\boldsymbol{r} = \boldsymbol{F}(\boldsymbol{r}, t), \tag{8}$$

(such as ours!) we may rewrite our differential equations as:

$$\boldsymbol{r_{i+1}} = \boldsymbol{r_i} + \Delta t \cdot \boldsymbol{v_i} + \frac{(\Delta t)^2}{2}\boldsymbol{a_i}$$
$$\boldsymbol{v_{i+1}} = \boldsymbol{v_i} + \frac{\Delta t}{2}(\boldsymbol{a_{i+1}} + \boldsymbol{a_i}). \tag{9}$$

Note that the velocity depends on the acceleration at time $t_{i+1}$. This is a function of $\boldsymbol{r_{i+1}}$ which needs to be calculated first. The error in this method goes like $\mathcal{O}(\Delta t^3)$ locally, which means we get a global error $\mathcal{O}(\Delta t^2)$, compared to Euler's method which has a total error $\mathcal{O}(\Delta t)$.

## C. Conservation laws

In Newtonian mechanics, for a system of objects without any external forces we have three fundamental conservations laws: The conservation of energy, the conservation of momentum and the conservation of angular momentum.

For the solar system, if we neglect any forces other than the pure Newtonian gravitational force (and the celestial objects are taken to be point masses) we may write the total energy as

$$E_{tot} = \sum_{i \neq j} \frac{1}{2}m_i v_i^2 - \frac{Gm_i m_j}{r_{i,j}}, \tag{10}$$

This is a conserved, or time invariant quantity; that is to say it must be the same in our calculations for all times $t_i$.

The total momentum of the system (no external forces applied) is also a conserved quantity and can be given as

$$\boldsymbol{p_{tot}} = \sum_i m_i \boldsymbol{v_i}. \tag{11}$$

If we wish to study our system from the gravitational center of mass at the origin with $\boldsymbol{p_{tot}} = \boldsymbol{0}$ we require

$$m_1 \boldsymbol{r_1} + ... + m_N \boldsymbol{r_N} = \boldsymbol{0}$$
$$m_1 \boldsymbol{v_1} + ... + m_N \boldsymbol{v_N} = \boldsymbol{0}. \tag{12}$$

This gives us $N - 1$ degrees of freedom to choose the initial positions and velocitites. We can then fullfill these conditions by requiring the sun to have an initial position and velocity

$$\boldsymbol{r}_\odot = \frac{1}{M_\odot}(m_2 \boldsymbol{r_2} + ... + m_N \boldsymbol{r_N})$$
$$\boldsymbol{v}_\odot = \frac{1}{M_\odot}(m_2 \boldsymbol{v_2} + ... + m_N \boldsymbol{v_N}). \tag{13}$$

As Newton's second law gives us conservation of momentum, a rotational analog of Newton's second law gives us conservation of angular momentum. For a system unaffected by external torque, the total angular momentum is conserved.

$$\boldsymbol{L_{tot}} = \sum_i \boldsymbol{r_i} \times \boldsymbol{v_i} \tag{14}$$

Note that momentum, energy and angular momentum will constantly be exchanged between the objects of the system via the gravitational forces, and these conservation laws are only valid when examining the system as a whole. If we didn't model the celestial objects as point particles there could also be several extra degrees of freedom in which energy and momentum could be distributed, but this is negligible for our purposes.

### D. Celestial mechanics

For a planet in orbit around a much more massive celestial object of mass $M$, we may find the escape velocity of the planet by finding the minimum kinetic energy required to move the planet infinitely far away. We thus acquire an analytical expression:

$$v_{esc} = \sqrt{\frac{2GM}{r}}. \qquad (15)$$

When considering the Earth-sun system this is simply $v_{esc} = \sqrt{8\pi^2}$, when expressed in $AU/yr$.

For a planet (mass $m$) in uniform circular orbit around a much more massive object of mass $M$ we have that the distance between the objects $r = $ constant. From equation (10) this implies that the potential energy is a conserved quantity. By studying for example the expression for the centripetal acceleration $a = F(r)/m = v^2/r$ it is easy to see that the speed must be constant and therefore the kinetic energy must be conserved.
From vector calculus we find for circular motion that $\boldsymbol{r} \perp \boldsymbol{v}$, and from equation (14) we obtain conservation of angular momentum.
As the velocity is constantly changing, the vector momentum $m\boldsymbol{v}$ is not conserved. The scalar quantity $mv$ is however (as speed is constant).
The speed $v = |\boldsymbol{v}|$ is easily obtained for the Earth-sun system, $v = 2\pi r/T = 2\pi AU/yr$.

### E. Mercury's perihelion precession

In classical mechanics, using Newtons law of gravity, we will get closed elliptical orbits for a planet moving around the sun. The perihelion-position (the point where the planet is closest to the sun) for the planet will appear at the same place every orbit. In real life, this does not happen. What we see is that the perihelion-position will move slightly for every orbit for a planet around the sun. There are different factors in the universe that causes this to happen. One factor is the theory of relativity.
The perihelion-precession is the difference between the postulated classical and the observed movement of the perihelion-position. When subtracting all factors that causes the shift of the perihelion-position except for the theory of relativity, the value of the perihelion precession is $43''$ per century. [**?** ]

When simulating this in our project, we add a relativistic correction to the classical force, so we get

$$F_{1,2} = \frac{GM_1M_2}{r^2}\left[1 + \frac{3l^2}{r^2c^2}\right] \qquad (16)$$

where $l = |\vec{r} \times \vec{v}|$ is the magnitude of the planets orbital angular momentum per unit mass and $c$ is the speed of light in vacuum. We looked at a simulation of Mercury and the sun for a century, and found all the perihelion-positions. We could then calculate the angle $\theta_p$ by

$$\tan\theta_p = \frac{y_p}{x_p} \Rightarrow \theta_p = \arctan(\frac{y_p}{x_p}) \qquad (17)$$

where $y_p$ and $x_p$ are the $x$ and $y$ coordinates at the perihelion. The perihelion precession is then given by

$$\theta_{p,classical} - \theta_{p,relativistic} \qquad (18)$$

### F. Object Orientation

A object oriented approach to our problem in short allows us to write the code once, and use it many times [**?** ]. As we are interested in celestial objects characterized by their position, velocity and mass; a class based approach lets us easily implement the properties and interactions of each celestial object in the solar system. In addition, it makes it quite easy to extend the code to include and calculate other properties such as the force on a single object or the total angular momentum of the system. We can also include other functionality such as writing to file or choosing the method of numerical integration without interfering with other parts of the code.

### G. Testing

As mentioned above, we have serveral conserved quantities to consider as we evolve our system in time. A test of whether the total energy of the solar system is conserved in time, or whether the angular momentum of a circular orbit remains zero at all times, is a good check to make sure our calculations are correct and sufficiently precise.

## III. RESULTS AND DISCUSSION

The masses of every planet is obtained from the table in project 3. The positions and velocities are obtained from NASA's website http://ssd.jpl.nasa.gov/horizons.cgi#top on

05.10.2016.

In our final implementation it is somewhat difficult to make an assessment of the total number of floating points operations involved, and questionable if it would be of much use. This is because the program involves a large number of function calls, if tests, vector operations and recalculation of quantities. Some of these inefficiences might be alleviated by an intelligent compiler. We do however find that the time usage scales roughly linearly with the number of time steps $n$.

TABLE (I)   Euler vs. Verlet method for y = 100 years

|  | Euler | | | Verlet | | |
|---|---|---|---|---|---|---|
| $\Delta t$ | $10^{-2}$ | $10^{-3}$ | $10^{-4}$ | $10^{-2}$ | $10^{-3}$ | $10^{-4}$ |
| $\Delta E_p/E_{p,0}$ | 8.537e-1 | 6.567e-1 | 3.329e-1 | 9.734e-4 | 9.870e-6 | 9.869e-8 |
| $\Delta E_k/E_{k,0}$ | 8.263e-1 | 6.570e-1 | 3.333e-1 | 9.334e-4 | 9.870e-6 | 9.873e-8 |
| $\Delta E/E_0$ | 8.400e-1 | 6.569e-1 | 3.331e-1 | 2.042e-5 | 1.009e-11 | 2.095e-11 |
| $\Delta L/L_0$ | 1.449e1 | 7.064e-1 | 2.240e-1 | 1.430e-3 | 1.444e-5 | 6.433e-6 |
| time usage [s] | 0.1362 | 1.391 | 14.66 | 0.1475 | 1.459 | 14.11 |

From this table we can see that while the Euler and Verlet method both scale linearly in time, the improvements in accuracy from the Verlet method are huge.
The Euler method has an error that goes from roughly 80 % to 30%, so there is little improvement to be made from reducing the time step. The gain in angular momentum is also very significant. This is likely due to the fact that the Euler method will consistently overshoot it's mark in a circular orbit, and will form a somewhat stable ellipse as errors accrue. The variations in total energy, and kinetic and potential energy are not too large from a slightly bent ellipse. However, a circular orbit always has zero angular momentum, while the ellipse does not, as the position and velocity must be orthogonal in circular motion.

For the Verlet method, we can see that the error scales roughly as $n^2$, which is a large improvement. In addition, both potential and kinetic energy are fairly well conserved, while the results for total energy are very good. In addition, angular momentum is about as well conserved as potential and kinetic energy, which suggest
### A.   Earth-Sun system

### B.   Earth-Sun system

We have already found an expression for the speed required for a stable circular orbit, equation (**??**). I tested the stability of the circular orbit for a time step $\Delta t = 10^{-3}$ years over 100 years. I tested the speed in the area $v \in (0.9, 1.4) \cdot 2\pi$, and find that this produces stable elliptical orbits. Too small initial velocity, the Earth will be hurled towards the sun, and the mutual force will go to infinity, producing round-off errors.
A initial velocity approximately the escape velocity $v = \sqrt{2} \cdot 2\pi \approx 1.4 \cdot 2\pi$ and the Earth will escape the sun's gravitational pull.
I test the stability of the Euler and Verlet algorithms for time steps $\Delta t = 10^{-2}, 10^{-3}, 10^{-4}$ and check the conservation of energies and angular momentum. I check the relative error between $t = 0$ and $t = 100$ years. $L$ is the length of the angular momentum vector. The results are recorded in table 1, the values are absolute values.

that numerical errors slightly perturb the circular orbit and we obtain a slight elliptical orbit.

### C.   Escape velocity

We looked at a planet which started at a position $1AU$ from the sun, and we were to find its escape velocity. Using equation 15 we found that the escape velocity for the Earth-Sun system should be $v = \sqrt{8\pi^2}$. When doing this numerically, we started by using the exact escape velocity and multiplying this by numbers close to 1 (see Figure 1)
(a)

FIG. (2)   The three-body problem where Jupiter is the red graph and the earth is the green. The motion of the sun can barely be seen as the blue graph.

(b)

FIG. (1)   Eart-Sun system with Earth's escape-velocity

We can see that for the initial escape velocity we found theoretically, the planet does escape. As the figure shows, there is some numerical error here, since the planet also escapes with an initial value smaller than the theoretical escape-velocity.

### D.   Three-body problem

In Figure 2 we have included three dimensional picture of the three-body problem where we have used the Verlet method for integration.

The plot in Figure 2 reproduces what we would expect to see in real life with the planets moving around the sun. Comparing this image to Figure 3 where we have increased the mass of Jupiter by 10 and 1000 we can see that we have two different-looking systems.

off errors. This is also the case when Jupiter's mass is multiplied by 10, while for the case where Jupiter's mass is multiplied by 1000, we get the change in energy

$$\Delta_E = 0.042 \qquad (20)$$

Both the lack of conserved energy and the chaotic-looking plot when Jupiter's mass is multiplied by 1000 tells us that there is lack of stability in this situation using the Verlet solver. With this being said, the Verlet solver keeps its stability in the situation most relevant to us when we are observing Jupiter, Earth, and the Sun with their respective masses.

(a) $M_{Jupiter} \times 10$

### E. Mercury's perihelion precession

In this project we looked at Mercury's perihelion-precession by adding a relativistic correction to the force (equation (16)) and compared the angle at perihelion (equation (17)) to the situation with classical Newtonian gravitational force.

To get the right precision in this part of the project it was crucial to have enough steps for integration. In Table II we have shown the time and the perihelion precession for two different numbers of integration-steps. The perihelion precession is calculated by Equation (18) for the $\theta_p$ values after a century.

(b) $M_{Jupiter} \times 1000$

FIG. (3)   Earth-Sun-Jupiter three-body system for bigger values of $M_{jupiter}$

TABLE (II)   Perihelion precession for different timesteps using the Verlet solver

| Integration steps $n$ | Time [$s$] | Perihelion precession ["] |
|---|---|---|
| $10^8$ | 0.3 | 47.72 |
| $10^5$ | 234.3 | 165.0 |

The situation with $M_{Jupiter} \times 10$ looks different, but it still looks like a stable system. The sun is pulled by both Jupiter and Earth, and this causes the whole three-body system to drift. The other system with $M_{Jupiter} \times 1000$ looks more unstable than the two other systems. We can also see this by looking at the conserved energy. For the system where we don't change Jupiter's mass, we get the change in energy

$$\Delta_E = 2.0 \times 10^{-8} \qquad (19)$$

which we can approximate as zero, because of round-

We expected the perihelion-precession to be $43''$. For $n = 10^8$ integration-steps we get an answer that is close enough to show that this is caused by relativistic correction. Also, if we were to to more integration-steps, our computers would spend too much time doing it. In Figure 4 we have included a plot for Mercury's perihelion precession. From this we can see that the precession between the classical case and the relativistic case gets bigger as time goes by.
FIG. (4)  Perihelion precession for Mercury around the sun for a century. The blue graph represent the classical case and the red graph represent the relativistic case. This is done with $n = 10^8$ integrationsteps

In Figure 4 the values of the angels $\theta_p$ is not what we are looking for, as these values can come from numerical errors in our program etc. The important thing is the difference between the plots, as calculated in Table II. As said above, the value we get for $\theta_p$ leads us to the conclusion that the perihelion precession is caused physics explained by the theory of relativity.

## IV.  CONCLUSION

We have found that for moddelling the solar system, the Verlet method does a much better job than the Euler method.  This includes maintaining the eccentricity of the orbit, and conserving vital quantities.  We have found that the methods scale similarly in time usage, which gives the Verlet method a good tradeoff in time usage vs.  accuracy.  It is also likely that the Verlet method is a good method for solving other systems where the force is governed by a potential.
For the Earth-Sun-Jupiter system we find that unless the sun is at least $10^3$ times more massive than the Earth and Jupiter we get highly chaotic results, and eventually large round off errors. This suggests that the stability of our solar system is highly dependent on the

sun being much more massive than the other celestial objects.  This is also seen when we test for different velocities of a single planet revolving around the sun. And we see that a not very large increase or decrease in kinetic energy is sufficient to send the planet either hurling towards the sun, or off into space.

Finally we find a purely relativistic effect for the perihelion precession of Mercury.  We find that this effect, 47", is so small that a very large number of time steps, roughly $n = 10^9$ with the Verlet method is required for sufficient accuracy.  And since this effect is on the time scale of centuries, it means that the newtonian theory of gravity is very robust on our length and time scales.

Object orientation makes this project mostly easy. However it has been very time consuming. The exercices we were required to perform I feel did not flow naturally from our implementation.  We found that the full 3D solar system was relatively easy to implement and plot. And in contrast to the theory in the exercise, I found it much more natural to directly implement the full equations of 3D motion rather than 2D.

The final version of our code contains a few inefficiences and parts that could easily be abstracted for reuse. We did for example not feel compelled to write unit tests for the program, as it was simple enough to just directly obtain and calculate for example energies from the solar system objects. In addition the code contains a few possibly unnecessary if-tests and numerous function calls which could possibly be improved upon. Due to time constraints we do not feel compelled to go back and rewrite, and the code is largely well-commented.

Finally the Mercury problem was quite hard to produce sensible results from, and it could have been made clearer that a large number of time steps $n$ was necessary to observe a noticable effect.  This also required some hacky code to produce the results, as our method of writing to file was not well suited for large $n$.

## V.  APPENDIX

All code used is available at: The programs used in this project are listed in this section:

**main.cpp:** Program1

**plot.py:** Program2
